

1 Description

2

3 OPTICAL MODULE COMPRISING AN IMAGE SENSOR AND A LENS UNIT  
4 THAT IS SUPPORTED ON THE SENSITIVE SURFACE OF THE IMAGE  
5 SENSOR

6

7 The invention relates to an optical module with a circuit  
8 carrier, a semiconductor element arranged on the circuit  
9 carrier and a lens unit for projecting electromagnetic  
10 radiation onto the semiconductor element.

11

12 The invention further relates to an optical system with an  
13 optical module embodied in this way.

14

15 Generic optical modules and systems are used especially in  
16 automotive technology.

17

18 In such cases operation can be with electromagnetic  
19 radiation from different frequency ranges, in which case  
20 cumulatively to the visible light, with which applications  
21 in the exterior area of a motor vehicle typically operate,  
22 such as LDW (Lane Departure Warning), BSD (Blind Spot  
23 Detection), or (Rear View Cameras), the infrared light which  
24 is invisible to the human eye is preferred for applications  
25 in the interior of the motor vehicle such as OOP (Out of

Position Detection), or for additional outside illumination of a night vision system.

High demands are imposed on applications in the interior and exterior area of a vehicle as a result of external influences such as temperature, moisture, contamination and vibration. The typical lifetime for systems in the motor vehicle is around 10 to 15 years, with only extremely low failure rates being tolerated, so that the components of an optical system of the type mentioned at the start may only exhibit very slow ageing.

Since in many cases the space for installing optical modules or optical systems is very restricted, additional difficulties arise in implementing the optical systems. It is thus extremely difficult using conventional means to construct a hermetically sealed reliable unit consisting of a camera chip (currently CCD or CMOS sensors) and optics.

To achieve sufficiently sharp focus for a camera system, consisting of an image sensor (currently CCD or CMOS) and a lens system, the sensor and optics components must be matched geometrically very precisely to one another. The tolerance range for the distance from the camera chip to the optics in the z-axis usually lies in the range of a few

1 hundredths of a millimeter to enable an optimally sharp  
2 image to be achieved for a specific depth of field. This is  
3 particularly a problem for so-called fixed-focus systems,  
4 since this tolerance which is small in any event may be  
5 exceeded during manufacturing. An additional consequence of  
6 an offset of camera chip to optics in the x- or y-axis is  
7 also that under some circumstances the optical system  
8 "squints", i.e. the image is truncated on one edge  
9 (horizontal or vertical), since the offset means that pixels  
10 are no longer present here and would have to be provided as  
11 a precaution.

12  
13 A further problem is presented by "tilt", i.e. a  
14 misalignment of the camera chip around the x- or y-axis,  
15 resulting in the image exhibiting an out-of-focus gradient  
16 in the horizontal or vertical direction. In addition a  
17 "rotation" can also be produced, i.e. a rotation around the  
18 z-axis of camera chip to optics.

19  
20 Almost all camera systems currently on the market which are  
21 supplied with a fixed focus setting need an additional  
22 compensation step during manufacturing, in which the  
23 distance from camera chip to optics along the z-axis is set  
24 and is fixed at this value. This is done for example using a  
25 thread and a corresponding adjustment screw or a glue

1 connection. A compensation step can also be necessary for  
2 the x-y offset or, if this is not done, a correspondingly  
3 larger sensor can be provided which provides more pixels to  
4 allow for the tolerances. Software which processes or  
5 calibrates out the rotation is also known. Since otherwise  
6 sharp image information is present, the pixels only need to  
7 be reassigned in a type of "calibration" process. However  
8 there can no longer be any information at the edges or  
9 corners since these are truncated. Finally, a purely  
10 mechanical reduction of "tilt" and "rotation" between chip  
11 and optics can as a rule only be achieved with usual systems  
12 by high-precision manufacturing and assembly or by  
13 calibrating the components.

14  
15 However cameras for specific low-cost applications such as  
16 automotive, industry, digital camera, mobiles, toys etc.  
17 should be manufactured from the standpoint of cost and of  
18 quality assurance aspects where possible without adjustment  
19 procedures between optics and camera chip, that is without  
20 making adjustments to the focus on the optical surface of  
21 the CMOS or CCD sensor. This basically conflicts with the  
22 stated requirements.

23  
24 One possibility for developing a focus-free system is to  
25 reduce the sums of the possible tolerances and elements, so

1 that the module or system functions as a result of the  
2 design without adjustment in at least one specific distance  
3 and temperature range. Where the invention is used for  
4 example within the framework of an occupant protection  
5 system of a motor vehicle, to which the present invention is  
6 however not restricted, sharper images at distances of for  
7 example 15 cm to 130 cm as well as at temperatures of for  
8 example - 40°C to + 105°C should be able to be guaranteed.

9 The fewer elements are included in the tolerance chain, the  
10 easier this is to implement. A large element in the  
11 tolerance chain is taken up by the circuit carrier for the  
12 camera chip (currently CCD or CMOS for example). Thus,  
13 especially with unhoused chips, an attempt is made, for  
14 example by using very thin, so-called flexible circuit  
15 carriers, to include only a very small thickness tolerance.  
16 With housed semiconductor elements the soldered or glued  
17 connections or such like necessary between the chip and the  
18 circuit carrier in particular constitute a large element in  
19 the tolerance chain.

20  
21 Using only one lens avoids additional optical tolerances  
22 being caused by a complicated lens construction. The lens  
23 holder, which is preferably made of plastic, can itself be  
24 connected to the lens arrangement in different ways so that  
25 an exact optical alignment of the lens arrangement and of

1 the semiconductor element in relation to the lens holder or  
2 the lens arrangement respectively can always be ensured.

3  
4 However with systems which largely feature a classical  
5 layout consisting of lens and camera chip, with the camera  
6 chip or the semiconductor element being accommodated in a  
7 housing or also unhoused as a so-called flip-chip or bonded  
8 onto a suitable circuit carrier, it is difficult to get  
9 around the given overall problems and simultaneously meet  
10 the given quality requirements. With housed semiconductor  
11 chips it is true to say that only particular measures need  
12 be taken to protect the front of the package from outside  
13 light radiation or other environmental influences, since the  
14 chip package offers sufficient protection from behind, e.g.  
15 for the Silicon which lets through IR radiation. The lens  
16 itself must however be adjusted to the camera chip and  
17 feature a defined focusing. This is done at present using  
18 tolerance-prone adjustment options through screwing, gluing  
19 or such like, by means of which the lens is fixed relative  
20 to the camera chip on the circuit carrier.

21  
22 The object of the invention is to make available an optical  
23 module and an optical system with a semiconductor element  
24 arranged on a circuit carrier, in which the tolerances of  
25 the different components, especially between last lens

1 surface and the sensor surface, such as glued connections,  
2 lens holder tolerance, thickness tolerance of the chips or  
3 such like, are practically eliminated, so that with simple  
4 and low-cost assembly a reliable optical quality can be  
5 provided without adjustment and especially without focusing  
6 effort and can be maintained over the lifetime of the module  
7 or system.

8  
9 This object is achieved with the features of the independent  
10 claims. Advantageous embodiments of the invention, which can  
11 be used individually or in combination with each other, are  
12 specified in the dependent claims.

13  
14 The invention builds on the generic optical module in that  
15 the lens unit is arranged supported directly on the  
16 sensitive surface of the semiconductor element. In this way  
17 the range of tolerances which is available for the focusing  
18 can be kept as small as possible so that this only still  
19 comprises manufacturing tolerances of the lens unit itself  
20 with the thickness tolerance of the necessary circuit  
21 carrier and any possible glued connections needed or such  
22 like being advantageously completely eliminated by the  
23 inventive layout.

24  
25 In accordance with the invention the lens unit preferably

1 features a lens holder which is arranged supported on the  
2 sensitive surface of the semiconductor element, with  
3 preferably a frame-type area or supports or such like being  
4 embodied on the lens holder or at least on sections of it,  
5 on which the semiconductor element rests with its optical  
6 surface. The fact that the chip rests directly on a for  
7 example frame-shaped area of the lens holder allows on the  
8 one hand the distance and thereby the focus range to be  
9 advantageously kept within the required dimensions, on the  
10 other hand it reduces the tilting of the components in  
11 relation to each other to a minimum.

12  
13 In a preferred embodiment of the invention the lens unit  
14 features a support lens which can be disposed in a supported  
15 manner on the sensitive surface of the semiconductor  
16 element. This is preferably done by a design of the support  
17 lens being selected which features an essentially flat  
18 surface on the side facing away from the chip on which the  
19 camera chip rests directly.

20  
21 To avoid the system being adversely affected as a result of  
22 contamination particles caused by wear or other problems  
23 between the flat surface of the support lens and be  
24 sensitive area of the semiconductor element, an optical gel  
25 is preferably disposed between these two surfaces.

1  
2 As an alternative or in addition to a support lens with a  
3 flat surface, a support lens can be embodied such that the  
4 necessary distance to the camera sensor is implemented by a  
5 frame or supports or such like which are part of the lens.  
6 This can be easily implemented when plastic injection molded  
7 lenses are used, since here, in addition to the optically  
8 effective surface of the lens, regardless of whether this is  
9 embodied flat or classically concave, the edge area can be  
10 of almost any design. If the camera chip is not fabricated  
11 in a standard housing but for example in flip chip  
12 technology, this support can be obtained relatively simply  
13 since the chip surface is not covered here and can  
14 simultaneously serve as a reference.

15  
16 In a further embodiment of the optical module in accordance  
17 with the present invention there is provision for the  
18 semiconductor element to be arranged on the side of the  
19 circuit carrier facing away from the lens unit and for the  
20 circuit carrier to feature an opening through which the  
21 electromagnetic radiation is projected from the lens  
22 arrangement onto the semiconductor element. The optical  
23 module is thus constructed in the sequence lens  
24 arrangement/circuit carrier or flexible circuit  
25 board/semiconductor element respectively. Even if

embodiments are conceivable in which the sequence of circuit carrier and semiconductor element is reversed, it has proved particularly advantageous to provide the circuit carrier with an opening and thus allow the first sequence given above.

Especially preferably an embodiment of the frame-shaped area of the lens holder or the lens is then such that it firstly: is at least as large as the optically effective surface of the camera chip; and secondly: is only slightly smaller than the window in the substrate (e.g. flexible circuit board), on which the camera chip is mounted. With this type of embodiment a type of self centering can advantageously occur which guarantees the exact positioning of the chip in relation to the optics as regards the x- and y-axis and also reduces the "tilt" to a minimum.

In accordance with increasing miniaturization requirements the semiconductor element is preferably arranged unhoused on the circuit carrier as what is known as a flip chip, since the flip chip needs up to 40 % less and thus significantly less circuit carrier surface when compared to a housed chip. In addition the desired lower position tolerance between the sensor chip and the circuit carrier in all three spatial directions can be achieved more easily by using flip chip

1 technology. The "contact peaks" located on the semiconductor  
2 connection surfaces, such as solder balls, stud bumps etc.,  
3 are connected to the circuit carrier or to the substrate by  
4 soldering, gluing or bonding. To obtain a reliable optical  
5 module in respect of environmental requirements such as  
6 temperature, humidity and mechanical shock, the practice of  
7 underfilling the semiconductor component with an underfiller  
8 is known. So that the underfiller flows into the gap between  
9 semiconductor element and circuit carrier and underfills the  
10 chip well it possesses a comparatively low viscosity and  
11 good flow characteristics. This in its turn has the  
12 disadvantage that, because of the space restrictions, the  
13 sensitive surface of the semiconductor element can be wetted  
14 in the edge areas and the corners so that the said areas are  
15 frequently no longer completely operable. In accordance with  
16 the invention the frame-shaped area of the lens holder or of  
17 the support lens is advantageously embodied enclosed so that  
18 the frame thus embodied, serving primarily a support  
19 function, also functions as a barrier against the flow of  
20 the underfill material, which advantageously prevents the  
21 underfill material which is introduced between chip and the  
22 substrate (for example a flexible circuit board) from  
23 wetting the optically effective surface of the semiconductor  
24 element.

1 In accordance with the invention the lens unit or the lens  
2 holder is preferably connected to the circuit carrier away  
3 from the opening embodied in the circuit carrier, especially  
4 glued, laser welded, screwed and/or in other such ways, so  
5 that a connection between circuit board and lens unit or  
6 lens holder is made available which fixes the inventive  
7 support of the lens unit on the semiconductor element and  
8 practically excludes any additional uncertainty as regards  
9 the optical quality of the module.

10  
11 The invention further comprises an optical system with an  
12 optical module of the type stated above. In this way the  
13 advantages of the optical module can also be brought to bear  
14 within the framework of an overall system.

15  
16 The invention is based on the knowledge that by supporting  
17 especially the lens holder lens or the lens edge area  
18 directly on the surface of the chip a camera module can be  
19 constructed in which it is possible to dispense with any  
20 mechanical focus setting. Thus the module can be  
21 manufactured fully automatically, which with large volumes  
22 has the advantage of lowering manufacturing and assembly  
23 costs. Furthermore the optical module can be developed  
24 without moving parts such as threads or fixing screws, which  
25 results in a higher reliability. The smaller tolerances of

the design, including in the x- and y-axis, mean that the chip surface does not have to be unnecessarily large, which makes the camera chip cheaper. Such a module can be a very compact design which has the advantage of allowing the camera module to also be used in applications where space is restricted.

The invention can be employed especially usefully in the implementation of video systems, if necessary in combination with radar systems, ultrasound systems or such like in the automotive area.

The invention is now explained with reference to the accompanying drawings by preferred embodiments.

The figures show schematic diagrams of:

Fig. 1 the cross-sectional view of a first exemplary embodiment of the inventive optical module with a lens holder, on which a frame for supporting the module on the semiconductor element is embodied;

Fig. 2 an enlarged section X of the optical module shown in Fig. 1;

1 Fig. 3 the cross-sectional view of a second exemplary  
2 embodiment of the inventive optical module with a  
3 support lens on which supports for supporting the  
4 module on the semiconductor element are embodied;  
5

6 Fig. 4 an enlarged section Y of the optical module shown  
7 in Fig. 3;  
8

9 Fig. 5 the cross-sectional view of a third exemplary  
10 embodiment of the inventive optical module with a  
11 support lens on which a flat surface for  
12 supporting the module on the semiconductor element  
13 is embodied; and  
14

15 Fig. 6 the support lens shown in Fig. 5 in an enlarged  
16 perspective view.  
17

18 In the description of the preferred embodiment of the  
19 present invention below the same reference symbols refer to  
20 the same or comparable components.  
21

22 Fig. 1 shows the cross-sectional view of a first exemplary  
23 embodiment of the inventive optical module with the lens  
24 unit 14; 16, 18, 20; 21, which comprises a lens holder 14,  
25 on which, to support it on the semiconductor element 12, a

1 frame 32 is embodied in at least sections of the holder (cf.  
2 also Fig. 2). The semiconductor element 12 can be designed  
3 in accordance with current technology, e.g. as CMOS or CCD.  
4 The connection between the semiconductor element 12 and the  
5 circuit carrier 10, on which further electronic components  
6 39 can be arranged, is preferably made using flip chip  
7 technology, by establishing a solder connection via solder  
8 bumps 30. Since with flip chip technology the sensitive  
9 active surface 34 is facing the substrate 10, a  
10 corresponding opening 24 must be present in the circuit  
11 carrier 10 or substrate so that electromagnetic radiation  
12 can reach the surface 34 of the semiconductor element 12  
13 sensitive to electromagnetic radiation. In addition to or as  
14 well as the solder connection 30, a glued connection (not  
15 shown) can also be provided. In any event it is worthwhile  
16 subsequently reinforcing the connection with an underfill  
17 material 31. Especially in these cases it is preferable in  
18 accordance with the invention to embody the frame 32  
19 enclosed so that this frame 32 simultaneously acts as a flow  
20 barrier and can prevent underfill material 31 wetting the  
21 optically effective surface 34 of the semiconductor element  
22 12. To protect the expensive semiconductor element 12  
23 against environmental influences its cover is provided with  
24 a Globtop 26.

1 Fig. 2 shows an enlarged section X of the optical module  
2 shown in FIG. 1. It is particularly evident that the circuit  
3 carrier 10 is embodied as a thin flex-PCB and is glued to  
4 the lens holder 14, for example using a thin double-sided  
5 adhesive strip 22. On the opposite end of the flex-foil 10  
6 the foil is provided with solder pads 28 so that preferably  
7 without the effort of a further electrical connection,  
8 contact can be established between the optical module and a  
9 rigid circuit board (not shown), for example through hot bar  
10 soldering using the solder pads 28. As an alternative to  
11 this, depending on the design and/or appropriateness to the  
12 circuit carrier 10, a corresponding electrical connection  
13 can also be implemented using a ribbon cable (not shown). To  
14 allow ventilation of the optical module, particularly with  
15 wide variations in temperature, a slot (not shown) for  
16 ventilation can be provided, for example in the adhesive  
17 strip 22. Likewise it is possible to arrange a glued  
18 pressure equalization element on an opening (not shown).

19  
20 In the lens holder 14 in accordance with Fig. 1 a lens  
21 arrangement with a number of lenses 16, 18, 20 and if  
22 necessary a diaphragm 21 in form of a package is preferably  
23 used. The optical quality can be improved by a lens with a  
24 number of lenses, which is also possible within the  
25 framework of the present invention, especially since it is

possible to work with fine tolerances here. In this connection it is also especially advantageous for the lenses 16, 18, 20 and also the diaphragm 21 to be formed so that they assume a defined position relative to one another within the lens holder 14. Furthermore at least one of the lenses 20 is designed so that it interacts with the lens holder 14 and thus assumes a defined position in relation to the lens holder 14 and in the final analysis, as a result of the lens holder 14 being supported on the semiconductor element 12, it assumes a defined position in relation to the latter 12. In this way all lenses 16, 18, 20 and where necessary diaphragms 21 are adjusted in relation to a semiconductor element 12. This adjustment is not influenced by further measures since the lens holder 14 is supported directly on the semiconductor element 12.

Fig. 3 shows the cross-sectional view of a second exemplary embodiment of the inventive optical module with a support lens 16 on which supports 33 to support the module on the semiconductor element 12 are embodied. Likewise the support lens 16 can be embodied so that the necessary spacing to the camera sensor 12 is implemented at least in sections by a frame (not shown) or such like.

Fig. 4 shows an enlarged section Y of the optical module in

1 accordance with Fig. 3. Supports 33 or frames are part the  
2 lens 16 and can be easily implemented especially when  
3 plastic molded lenses are used, since here in addition to  
4 the optically effective surface of the lens the edge area  
5 can be designed in almost any form.

6  
7 Fig. 5 shows the cross-sectional view of a third exemplary  
8 embodiment of the inventive optical module with a support  
9 lens 16 on which a flat surface 17 to support the module on  
10 a semiconductor element 12 is embodied. Unlike the previous  
11 drawings, the diagram in Fig. 5 clearly shows that the  
12 semiconductor element 12 can of course be a housed chip 12  
13 and the circuit carrier can be a rigid PCB 10. The  
14 connection between lens unit and circuit carrier can  
15 initially be fixed by an adhesive strip 22 and finally fixed  
16 by means of screws 23.

17  
18 Fig. 6 finally shows the support lens 16 in accordance with  
19 Fig. 5 with its flat support surface 17 in an enlarged  
20 perspective diagram.

21  
22 The present invention, by supporting the lens holder or the  
23 lens or the lens edge area directly on the chip surface,  
24 allows the construction of a camera module in which any kind  
25 of mechanical focus setting can be dispensed with. Thus the

1 module can be manufactured fully automatically, which with  
2 large volumes has the advantage that manufacturing and  
3 assembly costs are reduced. Furthermore the optical module  
4 can be developed without moving parts such as threads or  
5 fixing screws, which results in a higher reliability. The  
6 smaller tolerances of the design, including in the x- and y-  
7 axis, mean that the chip surface does not have to be  
8 unnecessarily large, which makes the camera chip cheaper.  
9 Such a module can be a very compact design which has the  
10 advantage of allowing the camera module to also be used in  
11 applications where space is restricted. Furthermore the  
12 layout described offers the opportunity of designing a  
13 hermetically sealed module which is protected against  
14 environmental influences such as moisture or dust. In the  
15 case of a flip chip construction the frame which is used for  
16 support can simultaneously be used as a protective barrier  
17 for the underfill material, i.e. prevent the material which  
18 is introduced between the chip and the substrate (e.g.  
19 flexible circuit board) from wetting the optically effective  
20 surface of the chip.

21  
22 The features of the invention disclosed in this description,  
23 in the drawings and in the claims can be of importance both  
24 individually and in any combination for implementing the  
25 invention. They are especially suitable for applications in

1 the interior and/or exterior area of a motor vehicle.
